Abstract. An attempt is made to examine the role of Anatolian and Caucasus mountain ranges in the precipitation distribution over the Black Sea region and to clarify the dynamical and physical mechanisms responsible for precipitation distribution over the region. Existence of a complex topography in the southern and eastern part of the Black Sea region makes it an important region for cyclogenesis. In this study the effect of Anatolian and Caucasus Mountains on the precipitating synoptic systems forming over the Black Sea are investigated. To this end, the Weather Research and Forecasting (WRF) model at 15-km horizontal grid spacing has been used to evaluate the lifetime of a low pressure system that was accompanied with heavy precipitation on 14 March 2009 over the coastal region of the Black Sea. Two experiments were conducted. In the control experiment (CTL), the topographical features of the region were retained. In the sensitivity experiment (EXP), the Anatolian and Caucasus mountain ranges were removed. It is found that in the EXP, some fields including vertical motion, relative vorticity, humidity, geopotential height in low level, cloud water content and precipitation distribution in the region undergo significant changes. As such, in the EXP, the vorticity, and the cut-off low system over the Black Sea intensified. It is also seen that, under favorable conditions for precipitation occurrence, the precipitation intensity in the south and east coasts of the Black Sea decreased and the region of maximum precipitation shifted toward the “Sea of Azov” region, in the direction of the surface southerly winds.

1 Introduction

High and wide mountain ranges act as a barrier against the atmospheric flows and make changes in the path of the flows at the other side of the mountains. Local effects of the mountains on atmospheric flows may create different climatic regions at the other side of the mountain ranges. For example, application of climate models show that without Tibet, Central Asian climate is relatively humid and from when Tibet was added, this area has become drier (Manabe and Broccoli, 1990).

It is known that, while ascending a mountain barrier, moist flow normally will enhance the precipitation over the windward slope and crest. Both modeling (Alpert and Shafir 1989, 1991; Sinclair, 1994, among others) and observational (Rhea, 1978; Pandey et al., 1999; Neiman et al., 2002, among others) studies have shown that the amount of precipitation depends on the intensity of the upslope flow. For example, Neiman et al. (2002) showed that the orographic precipitation over the coastal range of central California is correlated best to the altitude of the low-level jet and crest of the topography at around 900 hPa. Using a slab model, Alpert (1986) could predict the precipitation profiles across the Sierras, Himalayas, and Equadorian Andes. He concluded that slope-induced vertical velocities and decreased moisture availability with height are the main factors that mainly determine the precipitation distribution overhigh mountains.

Using the MM5 model, Cole (2004) investigated the relationship between orographic precipitation and the height and width of a barrier. He showed that maximum precipitation is highly dependent on the slope and width of the mountain as well as the horizontal wind velocity. The maximum
precipitation is a strong function of barrier slope for relatively weak upstream flow, such that a low (1000 m) and narrow (25-km half-width) barrier has a greater surface precipitation maximum than a high (2000 m) and wide (50-km half-width) mountain of equivalent slope.

Moradi et al. (2008) examined the impact of the Zagross mountain ranges in Iran on the distribution of precipitation over the Iran region. They showed that without the Zagross mountain ranges, under favorable conditions for precipitation to occur, more precipitation would take place over the central desert of Iran located in the leeward side of the Zagross. Hence, to examine the effect of topography on precipitation distribution over the region.

The aim of this article is to examine the role of Anatolian and Caucasus mountain ranges in the precipitation distribution over the Black Sea region and to clarify the dynamical and physical mechanisms responsible for precipitation distribution over the region.

Due to its peculiar morphology, physiographic characteristics and geographical location, the Mediterranean basin is an area prone to high-impact weather events, such as heavy precipitation or intense cyclogenesis (Davolio et al., 2009). Hence, to examine the effect of topography on precipitation distribution in the Black Sea region, a synoptic case was selected that caused heavy precipitation on 14 March 2009 over the coasts of the Black Sea.

The outline of this paper is as follows: The model setup is described in Sect. 2, and an overview of the synoptic situation is provided in Sect. 3. The results are summarized in Sects. 4 and 5.

2 Model setup

The Weather Research and Forecasting (WRF: Skamarock et al., 2001, 2008) model at 15-km horizontal grid spacing have been used. The model was run with two nested domains, with the larger domain covering the area that extends from 14° to 64° north and from 0° to 90° east and the smaller domain covers the Black Sea region from 25° to 50° north and from 20° to 60° east. The model has 27 sigma levels in the vertical with the top of the model set at a pressure of 50 hPa. The spatial resolutions are 45- and 15-km for the coarser and finer domains, respectively. Global terrestrial data including topography and land-use data with 2 min (~4 km) horizontal resolution were used to determine the topography and land-use on the model grid points. The initial and boundary conditions come from the operational 12Z runs of global forecasting system (GFS) of NCEP (National Center for Environmental Prediction) with one degree horizontal resolution. The selected options for the model physics are given in Table 1.

Two experiments were conducted. In the control experiment (CTL), the topographical features of the region were retained. In the sensitivity experiment (EXP), the Anatolian and Caucasus mountain ranges were removed. Figure 1 shows the model topography for the outer domain in the CTL and EXP. Also shown is the geographical location of the inner domain.

3 Synoptic situation

The topography around the Black Sea is highly variable. As shown in Fig. 1a, vast flat plain and low lands, with altitudes rarely exceeding 200–300 m above the sea level, are extended in the northern part. The Anatolian high plateau with its mountain elevations between 1000 to 5000 m is located in the south. In the east of the Black Sea, the Caucasus Mountains are located along the northwest – southeast direction. These high mountains include the Greater Caucasus mountain range in the northern part and the Lesser Caucasus Mountains in the southern part, with elevations having more than 2500 m at both ends and many peaks and heights with elevations of 4000 m or more.

In order to study the effect of Anatolian and Caucasus Mountains on precipitation distribution, a heavy precipitating synoptic system was selected that caused significant
amount of precipitation on 14 March 2009 in the northern, southern and eastern coasts of the Black Sea, covering parts of Ukraine, Russia, Armenia, Georgia, Azerbaijan, Turkey and Iran. Examining the synoptic weather charts for 14 March 2009 shows that a surface low pressure with 1010 hPa central pressure and northwest–southeast orientation is extended from the north of the Black Sea to Saudi Arabia (Fig. 2a). At 500 hPa level a cut-off low is formed at the northwest of the Black Sea and is associated with a strong trough with an axis of negative tilt, which makes a southerly upslope flow over the Anatolian mountain ranges (Fig. 2b). The upper trough at 500 hPa has not directly produced the southerly flows towards Anatolia, but has intensified the surface cyclone and thus the southerly flows have been initiated/intensified.

Figure 2c presents a satellite picture of Meteosat-7, showing the extended cloud coverage over the Black Sea at 00:00 UTC of 14 March 2009. Thick and high altitudes clouds can be clearly seen over the east and southeast of the Black Sea.

### 4 Results and discussion

The Weather Research and Forecasting (WRF) model, with the setup mentioned in Sect. 2, was used to simulate the lifetime of a low pressure system, from 12 March to 15 March 2009, which was accompanied with heavy precipitation from 12 to 14 March 2009 over the coastal region of the Black Sea.

To verify the model results in the CTL, we used the observed accumulated precipitation on 14 March 2009 at several synoptic meteorological stations located in the northwest and west of Iran. The model outputs and corresponding observations for 24-hr accumulated precipitation are presented in Table 2.

As is seen from Table 2, the model is successful in predicting the yes/no rain event and in general there is good agreement between the model outputs and observed values of precipitation.

Figure 3a and b shows the 24-hr precipitation forecast for the inner domain ending on 14 March 2009 for the CTL and EXP. As seen from the Fig. 3a, the results of the CTL shows extensive amount of precipitation on the southern, southeastern and northern coast of the Black Sea, with a maximum over southern part of Turkey and Iran. Results of the EXP (Fig. 3b) show a decrease in precipitation amount in the southeastern and eastern and an increase in northern and southwestern coasts of the Black Sea, with its maximum now found over Ukraine, north of the Sea of Azov. For example, the 24-h precipitation forecasts at the point located at 47° N and 38° E point at the north of the Black Sea, indicated by a star in the figure, are 30 and 55 mm for the CTL and EXP, respectively.

The enhanced precipitation in the southern part of Anato- lian mountains (Fig. 3) is due to the increased vertical motion and convergence of moist air currents. For the same reason a maximum of precipitation is seen in the windward side of the Caucasus Mountains. On the contrary, descending motions with reduced humidity over the northern part of moun- tains cause less amount of precipitation. After removing the mountains (EXP) the precipitation maxima is shifted to the region of “the Sea of Azov” (Fig. 3b).

To examine the change in the distribution of precipitation, some important fields including 700 hPa geopotential height, relative vorticity, relative humidity and vertical motion are presented and analyzed.

The 700 hPa geopotential height forecasts for 00:00 UTC 14 March 2009 for both CTL and EXP are shown in Fig. 4. In the CTL a cut-off low with a closed contour of 2800 m and its associated trough is seen over the north of the Black Sea that is extended over the Red Sea. In the EXP the cut-off low is deepened and its central height is reduced by 40 m.

Fig. 5. Forecasts of 700 hPa relative vorticity ($s^{-1} \times 10^5$) for 14 March 2009 at 00:00 UTC for (a) CTL and (b) EXP.

The 700 hPa relative vorticity forecasts for 00:00 UTC 14 March 2009 for both CTL and EXP are shown in Fig. 5. The pattern of relative vorticity in the CTL run (Fig. 5a) shows a narrow band of low values with a minimum value of $10 \times 10^{-5}$ located over the central Anatolia and extended to southeast of the Mediterranean Sea. For EXP this band is more continuous and its maximum value of $15 \times 10^{-5}$ could be seen over Syria. Also, higher values of relative vorticity are now located over the west of the Sea of Azov, which might intensify the cut-off low over the region. This could be the reason for enhanced precipitation over the Sea of Azov in the EXP. Increase in the values of relative vorticity is clearly related to the elimination of the mountain ranges from the domain and thus increasing the depth of the atmospheric column.

Figure 6a and b shows relative humidity and vertical motion at 700 hPa level. The overall pattern of the relative humidity is similar both in CTL and EXP. Though in the EXP, values of relative humidity and vertical motion ahead of the trough have increased, such that high values of relative humidity around 100% are now seen over the Sea of Azov and Ukraine. These increased values of relative humidity and vertical motion have a direct link with the intensification of the above mentioned cut-off low and hence vertical transport of moisture. For example, at the point located at 47° N and 38° E values of vertical motion in the CTL and EXP are 5 and 16 cm s\(^{-1}\). As is seen from the figure, after elimination of Anatolian mountain ranges from the domain, lifting vertical motion and hence vertical transport of moisture have been weakened.

Another quantity undergoing considerable changes is the cloud water content. To examine the changes in this quantity, a point with the maximum of precipitation in the EXP at 47° N and 38° E is selected. The vertical profile of cloud water content at this point for both the CTL and EXP with time is presented in Fig. 7. As seen from Fig. 7a, there is a maximum of $120 \times 10^{-6} \text{ kg kg}^{-1}$ at 850 hPa for 03:00–09:00 UTC on 14 March 2009, which has extended up to 550 hPa. In the EXP (Fig. 7b), on the other hand, the maximum is increased to $500 \times 10^{-6}$ and is seen at 900 hPa on 06:00 UTC 14 March 2009. Unlike the CTL, high values of cloud water content (exceeding $100 \text{ kg kg}^{-1}$) exist, starting from around 00:00 to 12:00 UTC on 14 March 2009. It is thus concluded that under favorable conditions for precipitation to occur, without Anatolian and Caucasus mountain ranges in the region, location of maximum precipitation is shifted towards the north of the Black Sea.
5 Conclusions

The Weather Research and Forecasting (WRF) model was used to simulate the role of the Anatolian and Caucasus Mountains on the precipitation distribution over the Black Sea area. Due to the air-sea contrast and thus existing baroclinicity at lower levels, the eastern and western coasts of the Black Sea are prone to cyclogenesis (Trigo and Davies, 1999). A heavy precipitation synoptic system was simulated with and without the Anatolian and Caucasus Mountains. It is found that without Anatolian and Caucasus Mountains, the fields of vertical motion, relative vorticity, humidity, geopotential height in low level, cloud water content and precipitation distribution undergo significant changes. The precipitation maximum is located over Ukraine and the Sea of Azov. Finally we conclude that the Anatolian and Caucasus Mountains are not responsible for cyclogenesis and formation of the cut-off low at middle levels, but act to weaken the existing cut-off low. As such, the most important role of the mountains lies in their impact on the precipitation distribution and humidity over the Black Sea area.
