Abstract. Planning for post-disaster accessibility is essential for the provision of emergency and other services to protect life and property in impacted areas. Such planning is particularly important in congested historic districts where narrow streets and at-risk structures are more common and may even prevail. Indeed, a standard method of measuring accessibility, through the use of isochrones, may be particularly inappropriate in these congested historic areas. Bucharest, Romania, is a city with a core of historic buildings and narrow streets. Furthermore, Bucharest ranks second only to Istanbul among large European cities in terms of its seismic risk. This paper provides an accessibility simulation for central Bucharest using mapping and geographic information system (GIS) technologies. It hypothesizes that all buildings in the risk 1 class would collapse in an earthquake of a similar magnitude to those of 1940 and 1977. The authors then simulate accessibility impacts in the historic centre of Bucharest, such as the isolation of certain areas and blockages of some street sections. In this simulation, accessibility will be substantially compromised by anticipated and extensive building collapse. Therefore, policy makers and planners need to fully understand and incorporate the serious implications of this compromised accessibility when planning emergency services and disaster recovery responses.
ability, especially when there are strong pressures for rapid development. Finally, the characteristically long time lags between pairs of strong earthquakes (Schweier and Markus, 2006) can dull public awareness of the potential impacts of such disasters and render those in charge of emergency management complacent.

Earthquakes require a specific disaster planning approach (Armaș, 2008; Boștenaru Dan and Armaș, 2015). This is because, unlike disasters that can be anticipated in the short term (such as storms), there is little or no delay between the occurrence of the earthquake and the subsequent loss of life and property damage. Therefore, emergency response activities must be executed very quickly and efficiently (Wegscheider et al., 2013). For cities with a high earthquake risk, an important factor is public awareness of such events. This conditions the population towards the importance of quick response measures, which can help to reduce property damage and, more importantly, the number of casualties (Armaș and Avram, 2008). However, no matter how well organized the mitigation process, the disastrous effects of major earthquakes cannot be totally avoided (Momani and Salmi, 2012).

Post-disaster recovery needs to transfer the most debated academic concepts (disaster resilience, for example) into appropriate politics and transform them into real tools for adequate planning. Governments have an important task: to prepare the population and all stakeholders for future similar events (Comerio, 2014).

In recent years, seismic risk management has been more fully studied and developed so as to establish a series of priorities related to the rehabilitation of those buildings considered to be of major importance, including schools (Grant et al., 2007; Raffaelle et al., 2013; Panahi et al., 2013), public institutions, historic buildings, and monuments (Grasso and Maugeri, 2009; Pessina and Meroni, 2009). Urban earthquake planning therefore needs to be more proactive (Boștenaru Dan et al., 2014), and there is a demonstrated requirement for coherent urban policies (Ianos et al., 2017) to mitigate the inevitable occurrence of blockage points during emergency interventions.

In emergency situations, the key response element is rapid accessibility to places where possible casualties may be located. Timely intervention within the first 2 h is critical in saving the wounded and in identifying the safest access routes for specific emergency equipment. As Friedrich (2007) suggests, the disaster responses made during the first 3 days are fundamental. After that, the main goals are invariably rescuing trapped victims and treatment of the injured, though ongoing fire control may also be required in some cases.

In general, natural hazard management includes the development of impact scenarios before the actual disasters occur (Bakillah et al., 2013). In this context, geographic information systems (GIS) techniques may be particularly useful in developing decision-making and response scenarios for potential earthquake disasters.

Our study shows that special attention should be paid to accessibility in the historic centres of large cities (Ianos and Cepoiu, 2009). Historic city centres are characterized by intense pedestrian traffic and by a high proportion of attraction points (clubs, restaurants, hotels, etc.) which result in high concentrations of people. Since the core of the historic centre of Bucharest is characterized by a high number of buildings that were strongly affected by earthquakes in the last century, we can reasonably speculate that determining their accessibility in an emergency situation will facilitate quick intervention in areas where injured people – either direct casualties or victims of earthquake-related phenomena such as fires, gas accumulations, or local flooding – are likely to be concentrated. The main objective of the study is to integrate geospatial data using thematic mapping products with GIS techniques in order to provide seismic risk management solutions for Bucharest. We therefore seek to provide concrete data and comprehensible information that can enable decision makers to implement and prioritize their disaster management strategies. A similar study, based on different hazard scenarios and a deep analysis on social vulnerability in Bucharest, identifies the importance of fire stations, hospitals, and parks in post-disaster situations (Armaș et al., 2016).

Unlike most studies of community response following an earthquake occurrence and the critical analysis of the emergency situations management generated thereby (Pollino et al., 2012; Wegscheider et al., 2013; Lu and Xu, 2014), the present study demonstrates the importance of GIS analyses in detecting potential congestion and inaccessibility issues in areas where buildings are most likely to collapse and accessibility issues are most likely to arise as a result of an earthquake.

2 Case study

Bucharest is Romania’s largest city (with over 2 million inhabitants), the national capital, and one of the great metropoles of southeastern Europe (GROSEE Espon Project, 2014). Its urban evolution has been very rapid, largely occurring from the second half of the 19th century. Currently, the city occupies an area of 228 km$^2$ and possesses a housing stock predominantly consisting of multifamily apartment buildings, built during the communist period (Ianos et al., 2016). Located about 135 km from the epicentre of the Vrancea seismic area (Lungu et al., 2000), in close proximity to the Southern Carpathian Mountains and at the junction of the Eastern European, Intra-Alpine, and Moesia plates (Mârnăureanu et al., 2011), the city is extremely vulnerable to earthquakes. Indeed, in a classification of European metropolitan areas with respect to potential loss of life and damage to property, Bucharest is ranked second after Istanbul (Bala, 2014).

The historical record of Bucharest is replete with accounts of damaging earthquakes ever since the city’s founding (Tat-
The Vrancea seismic area is responsible for the highest seismic risk in Romania (Pavel et al., 2014; Ardeleanu et al., 2005). Over the past 76 years, Bucharest has been affected by four earthquakes with a magnitude of between 6.9 and 7.7 on the Richter scale (November 1940, March 1977, August 1986, and May 1990).

The study area for this paper is confined to central Bucharest, an area of approximately 8.33 km² (Fig. 1). The oldest part of the city is situated in the south of this area, which comprises the historic centre (from the 16th and 17th centuries) and the central and northern parts dating from the 18th and 19th centuries. All four earthquakes mentioned above have impacted this case study area, with the most powerful being the earthquakes of 1940 and 1977. This sequence of earthquakes has had a cumulative effect, which explains the relative lack of buildings dating back more than 200 years.

The most serious problem is presented by the large number of buildings from the late 19th century within the historic centre, which has structurally degenerated over time and no longer meets the current building standards with regard to assessment of the ground motion levels for the Vrancea (Romania). Not only does Bucharest have a high level of exposure to earthquake hazards; it also suffers from poorly organized civil protection services and a low level of public awareness and education concerning these seismic risks (Armaş, 2006).

Nevertheless, anticipation and anxiety are building, given the length of time that has passed since the 1977 major earthquake. In essence, there is a fear that the city will be no better prepared than it was in 1940 (Fig. 2a) or in 1977 (Fig. 2b). These figures show only a slight improvement in the standard of the disaster measures between the two dates, and there is a growing recognition that greater levels of preparedness are needed.

Immediately after the earthquake of 4 March 1977, with about 1700 victims (Török, 2017), the former regime announced the start of a rehabilitation project for the highly degraded buildings within the central area, a project which was abandoned in less than a year. Many buildings, after being braced in position for 6–7 months with wooden or metal poles (which were later withdrawn), were then only “cosmeticized” and reoccupied. These decisions set a precedent for irresponsible policy that, unless it is addressed and altered, could have disastrous long-term consequences. Additionally, the growth of complacency over time has been a great enemy, and a permanent state of vigilance is needed. Finally, there is a need for considerable public investment in mitigation in the areas most vulnerable to earthquakes. The lack of wider public awareness of the high seismic risk of these buildings (identified as a result of surveys conducted in and since the mid-1990s) is evident in that the apartments in
these cosmeticized blocks are still among the most expensive in the city due to their central location and spaciousness.

Accordingly, the Romanian government has established the National Committee for Emergency Situations and the Department for Emergency Situations. The department coordinates the General Inspectorate of Emergency Situations. Forty-one local inspectorates cover the city of Bucharest and the department of Ilfov. The city of Bucharest has three exist-
ing meeting points (two in Bucharest and other in the village of Ciolpani to the north), and there is a special strategy to bring in instantaneous support from 24 counties surrounding the city.

3 Data and methods

This assessment of seismic hazard and vulnerability includes quantitative and qualitative data analysis that incorporates physical, environmental, social, and economic factors; potential impacts from existing risk maps; and estimates of the population that would potentially be affected (Mândrescu, 1990; Armaș, 2012; Rufat, 2013; Pollino et al., 2012). The accessibility analysis takes into consideration the specificities of each urban district, especially the urban context (Noto, 2017).

3.1 Data

The authors have used several data sets (buildings classified by seismic risk and emergency categories, i.e. the presence of hospitals and fire stations) in order to provide a realistic depiction of the impact that a potential earthquake could have in the historical centre of Bucharest. Only those fire stations and hospitals within the municipal limits of Bucharest are included. The main data sources were provided by public institutions. Every year the municipality of Bucharest publishes a technical report classifying buildings with relation to four seismic risk criteria and three emergency criteria to assess their level of public safety. Table 1 shows the distribution of Bucharest’s buildings by risk and emergency categories. Special attention is paid to the historic centre of Bucharest, which contains the largest concentration of buildings which represent a public safety risk.

To represent the accessibility patterns prior and subsequent to an earthquake, it was necessary to digitize all elements of the transport infrastructure, construction, green spaces, alleys, sidewalks, and property limits.

Several different map sources were used to identify building locations, including cadastral maps at scales of 1:500 and 1:2000 (IGFCOT, 1974–1975). Other map types and sources include old maps of Bucharest produced by the Topographic Military Directorate and orthophotomaps (2014) taken from the National Agency for Cadastre and Real Estate Advertising. The authors have overlaid accessibility patterns on a numerical model of the land, given the absence of natural barriers, since the municipality of Bucharest is located on a plain.

3.2 Methods

An important methodological contribution on the capacity of a city to resume urban functions after a seismic event is the study by Goretti et al. (2014) on how the Crotone urban system could better respond to such disasters. This study shows the importance of rapid accessibility to collapsed buildings and to injured people. Our study therefore emphasizes the importance of immediate accessibility for emergency intervention mechanisms and the need to provide information to facilitate the proactive actions of decision makers, who need clear and straightforward directions.

The main methodological steps in mapping accessibility in the central area of Bucharest were (a) setting up a reference database of all the buildings with seismic risk; (b) transferring this information to a detailed map of the identified buildings; (c) identifying indicators of building density and age, and traffic (including pedestrian) intensity; (d) showing the locations of all hospitals and fire stations; (e) calculating present-day (before a possible earthquake) accessibility levels; (f) identifying specific locations of potential congestion resulting from the collapse of buildings included in the highest risk class; and (g) determining, by simulation, the immediately inaccessible or poorly accessible areas for the intervention crews in the case of an earthquake, taking into account those buildings that might collapse if an earthquake occurs.

In the scientific literature, “access” is mainly measured as a physical distance or travelling time (Sotoudehnia and Comber, 2011). In this study, mapping the accessibility of the central area of Bucharest was completed using GIS techniques incorporating spatial analysis. The calculation of accessibility was initially based on the geometric structure of the public transport network (busses, trams, and underground services), but not on the walking and cycling networks, which, although they have been included in other studies, are less amenable to emergency service access in this context (Graeme and Aylward, 1999; Parker and Campbell, 1998; Naphtali, 2006; Svensson, 2010; Weiping and Chi, 2011; Sotoudehnia and Comber, 2011; ESPON TRACC Interim Report, 2011; ESPON GROSEE Final Report–Scientific Report, 2014; Blandford et al., 2012; Coffee et al., 2012; Yiannakoulias et al., 2013; Vojnovic et al., 2014).

The Kernel Density tool was used to calculate the density of points and line features in a neighbourhood around those networks. After modelling the road network using the ArcGIS Network Analyst extension, the authors used an assortment of analytical tools. These included the New Route tool to check the road network, the New Closest option to determine the closest emergency facility (hospital, fire station) to each point, and the New OD matrix function to determine optimal routes (depending on road distance and travel time) following the principle of the shortest possible route to establish links between each pair of points.

To highlight accessibility in the most comprehensive way, the street structure (which is very dense in the historic centre where the streets are narrow) and road traffic density had to be taken into account. Accessibility was calculated as a function of the distances between different buildings areas and hospitals and of the time necessary for these movements (using isochrones). Isochrones maps, showing travel times by

Source: processed data using the list of buildings with seismic risk, published by the municipality of Bucharest (http://amccrs.pmb.ro/docs/Lista_imobilelor_expertizate.pdf, last access: 15 October 2017).

In recent years, scientific approaches to risk reduction of natural events, such as earthquakes, have used resilience as an important concept, which could offer new theoretical and practical tools for better civil protection (Fekete and Fiedrich, 2018). Using this concept, scientists are paving the way for reinvigoration of the expectations, by joint actions with decision makers and civilians (Anhorn, 2018). These ideas ask whether other complementary issues are connected with a higher accessibility to the affected areas.

Our approach, focusing on the single issue of accessibility in a situation of crisis management, shows empirically how GIS technologies can be used to make recommendations to authorities to improve their preparedness levels and response speeds in post-earthquake interventions. Within this study, GIS is used solely as a tool to identify accessibility as a starting point for disaster management (Nushi and van Loenen, 2013). These GIS solutions are demonstrably important applications in relation to the first two phases (risk mitigation and disaster preparedness) of Alexander’s (2002) four-phase sequence of emergency management activities.

4 Results

It is necessary to simulate emergency interventions prior to the occurrence of catastrophic events because, in the local situation, the inherited intra-urban structure, with a narrow
The winding street pattern dating back to medieval times; the poor structural condition of many of the buildings; and limited access to important points from the emergency response activity locations are all of critical importance.

In such a context, accessibility to specific disaster sites is critical, and this requires that urban areas of this nature be treated with special attention. The biggest challenge may be caused by traffic congestion compounded by debris, which can isolate critical areas, making rapid intervention to put down fires and save human lives impossible.

The official identification of buildings with a high seismic risk combined with precise mapping of their location can be related to the density of road traffic in the historic areas (Fig. 3). If traffic is very high on the main access streets, this could inhibit rapid intervention, especially in a situation of general panic such as that generated by a potential earthquake. It would also be difficult to use narrow streets, where the pedestrian traffic and partially collapsed buildings could block the access of emergency service vehicles. In this context, there is a need for proactive measures, to mitigate the risk of late arrival of assistance at the affected buildings.

The most important area of the historical centre is the one delimited by Armenească, Moșilor, and Călărași streets; Splaiul Independenței; Calea Victoriei; and Carol and Regina Maria boulevards. Within this area, the building density exceeds 2.5 units ha$^{-1}$; in some places, it even exceeds 10 units ha$^{-1}$. In the areas of the highest density, most of the buildings have two or three floors, and, because of their uncertain legal status after 1990, many exhibit an advanced and increasing degree of dilapidation. Restoration and reinforcement of these buildings by both public authorities and private entrepreneurs are only proceeding at a maximum rate of two buildings per year.

The number of buildings with the highest seismic risk (computed with the Kernel Density tool) shows a very high concentration in the historical centre of Bucharest (Fig. 4). When looking at a map of seismicity at the level of Bucharest, it becomes obvious that the inherent risks from earthquake damage are greatest in central Bucharest, including the historical centre (Rufat, 2011). Even though most of the buildings located in the historical centre date from the early 20th century, they were built on the foundations of 19th-century structures (Armaș, 2008).

To highlight the anticipated degree of access for fire protection and ambulance services in the central area, accessibility levels prior to an earthquake were calculated and later compared to a post-earthquake scenario. Taking into account the location of the fire stations and hospitals, and the street tram network, the access routes into and within the study area were evaluated using the Network Analysis tool. Thus we identified the shortest routes from the closest emergency facilities (fire stations and hospitals) to all locations in the study area.
area, using the Bellman–Kalaba algorithm. These minimal road applications were applied for various types of emergency service: transport, ambulance, fire, police, etc.

It was noted that both firefighting and ambulance service accessibility were high or very high for most parts of the capital city, including the downtown area, which is especially well served by firefighter and ambulance services. There are 13 large fire stations in Bucharest. However, the lowest levels of potential accessibility by fire services to individual houses in the city of Bucharest occurred in the historic centre area, mainly due to the configuration of the street pattern (Fig. 5). The lowest values were registered in an area between Calea Victoriei, Doamnei Street, Brătianu Boulevard, and Splaiul Independenței, in the core of the historic centre. Low values occur to the east of Brătianu Boulevard, even though some important access axes (Armenească, Calea Moșilor, Hristo Botev, Negustori) are located nearby. Overall, if fires broke out at several different points in the historic centre core during a seismic event, this would present huge problems.

The map of ambulance accessibility (Fig. 6) presents a very similar picture. However, access is better in the northern part of the historic centre due to the location of Colțea Hospital. Figure 7 shows two areas where it would be difficult for ambulances to arrive in a timely manner, one in the core of the historical centre and the other in the surrounds of Mihai Vodă Street, which would be accessed by ambulances from University Emergency Hospital.

5 Discussion

Should an earthquake occur, an important consideration is the challenge presented by building collapses which obstruct road access. Identifying individual buildings with the highest levels of seismic risk highlighted the possibility of concentrated building collapses in certain locations within the historic centre. In these locations, some buildings would become isolated, and rapid intervention by fire or ambulance services would be impossible.

This general analysis indicates that the central area seems to be favoured due to the possibility of intervention from several emergency service points into this part of the city. However, and in spite of this, pedestrian and vehicular congestion is highly likely to inhibit rapid access by firefighters and ambulances in several areas within the central district. Also, several locations in the downtown area, which previously appeared to have high emergency accessibility levels, were shown to possess high probabilities of multiple building collapses. These events could well obstruct access by emergency vehicles, despite the high levels of accessibility that were identified initially.

Should an earthquake with a magnitude of over 7 on the Richter scale occur, fires would present a major associated risk. The majority of the city centre buildings are of timber construction or possess many timber components (some buildings from Șelari Street, e.g. “Crama Dom-

nească”; Covaci Street; and Smârdan Streets, for example). These buildings characteristically house restaurants, cafes, or pubs, which contain huge quantities of furniture, a further important source of fire. If emergency action does not occur promptly, in such locations, the probability of numerous fatalities is high. In addition, water supply and sewerage systems may be damaged, resulting in basement and ground floor flooding. It would therefore be advisable to provide supplementary emergency response materials at a large number of locations within this district. This would allow access to such equipment at the local scale as an alternative to the provision of emergency materials and services from elsewhere which may be unobtainable in the event of an emergency.

Assuming that, in the event of a large-scale disaster, certain clusters of buildings may become isolated and inaccessible to emergency services, it is therefore recommended that smaller-scale aid stations be established within these districts. These smaller-scale aid stations could then provide critical assistance in areas isolated by building collapses.

A detailed analysis highlights the fact that in the southwestern part of the historical center of Bucharest there is an area that includes several buildings of national importance (the parliament building, the headquarters of several ministries and other public institutions). In the proximity of this area are located several emergency services that may be oriented to ensure the protection of these public institutions, rather than the provision of services to areas with high densities of buildings with high seismic risk.

The map which shows both the distribution of the highest seismic risk buildings and the location of the nearest fire stations (Fig. 7) illustrates the need for greater proximity (and hence access) of fire stations to the two areas of maximum density of highest-risk buildings: one in the Lipsan area and the other in the Bălăței area. The western area (Grivița–Gara de Nord) could be placed under the authority of the two existing fire stations. These areas of high vulnerability should be connected to a permanent emergency water supply (since the normal water sources would be disrupted by an earthquake). They should also possess a minimum, yet sufficient, level of equipment for a local first response.

The location of hospitals again appears to be favourable at first glance (Fig. 8), but their capacity should be assessed against the probable number of casualties, which could reach as high as 11 000. The earthquake of 1940 registered 1271 and the 1977 earthquake 11 321 injured persons (Pavel and Văcăreanu, 2015). The location of Colțea Hospital suggests that the majority of injured persons would go there for immediate treatment. However, this hospital only possesses a small surgical unit (with three operating theatres), and it would be unable to offer emergency medical assistance to a large number of persons over a short period.
To increase the efficiency of emergency response, the location and number of potential casualties must be more precisely determined. Consideration needs to be given to the availability of specific medical services at individual hospitals and other medical facilities. The provision of surgical wards, imaging laboratories, and orthopaedic facilities is more uneven than the provision of hospitals more generally across the city. Depending on the territorial distribution of these specific hospital services, the buildings with highest seismic risk should be assigned to specific emergency hospital services so that accessibility levels can be maximized. Obviously, this implies the designation of dynamic territorial structures, which, depending on the gravity of the reported seismic events and their human consequences, would include access to other hospitals at greater distances from the central area (Toma-Dănilă, 2013).

There are some studies on firefighting simulation outside of the historical centre of Bucharest, for example on Magheru Boulevard, which reveal the importance given to this related phenomenon with an earthquake event (Fiedrich, 2007). In the event of a powerful earthquake, a partial or even total breakdown of communication systems is likely. This eventuality would cause many people to make direct contact with friends and relatives by moving around the city by car. Rapid intervention by the traffic police would be vital to minimize congestion in those areas of the city where the need for emergency intervention is greatest.

The unpredictable nature of this phenomenon may well lead to traffic bottlenecks at unanticipated locations along the transportation network, which in turn would further complicate rescue, relief, and evacuation efforts. In these circumstances, communication systems between those who would be mapping the collapsed or damaged buildings and those who would be ensuring the traffic flow need to function as smoothly as possible in order to allow the wounded to be transported to hospitals and the fire engines to move towards critical spots in the city. Where the simultaneous collapse of buildings, especially in the medieval area of the city, made rapid intervention impossible, lifesaving equipment, individually transported by specially trained persons, would be needed to provide immediate assistance.

Our study has sought to demonstrate what could happen in the core of the historic centre (Fig. 9), taking into consideration the likely collapse of buildings classified as risk 1 (R1). Any future earthquake of more than 7.2 on the Richter scale (the level of the strongest recent earthquake on 4 March 1977) would pose an amplified danger of the collapse of buildings at critical locations. We define critical locations as those where building collapse could block access to specific areas or street segments.
These potential blockages are most likely to occur in five areas, identified in Fig. 9 as A, B, C, D, and E. Area A (Blănar area) is small and delimited by building no. 2 (built in 1865, three floors) and the buildings from no. 9 (1880, five floors) to no. 14 (1935, six floors). Area B (Lipsani–Gabroveni area) is the largest site and contains a group of 15 vulnerable buildings. Possible street blockages could be produced by the collapse of buildings on Lipsani Street, such as no. 26 (1864, five floors) or no. 29 (1934, nine floors) along with no. 76 (1906, four floors), and on Gabroveni Street, such as buildings no. 2 (1940, nine floors) and no. 12 (1924, six floors). Two other areas, C and D, are respectively located on Franceză Street between buildings no. 6 (1869, five floors) and no. 22 (1900, six floors), and between buildings no. 30 (1870, five floors) and no. 42 (1870, five floors). On the west side of the main boulevard, Bulevardul Ion C. Brătianu, area E (Bărăţeii) contains building no. 8 on Baia de Fier Street (1930, five floors) and buildings no. 37 (1870, three floors) and no. 50 (1824, four floors) on Bărăţeii Street.

A final consideration is that, for much of the day, the core of the historic centre normally contains between 1000 and 5000 visitors in addition to the area’s residents and workers. This only adds to the need to devise proactive earthquake intervention and mitigation strategies.

We therefore suggest the following proactive measures to mitigate the risks associated with a seismic disaster in the city of Bucharest, especially within the core of the city’s historic centre:

- the constitution of a technical team of decision makers to identify optimal response strategies for a future earthquake, whose main task would be to identify the critical points and areas for emergency intervention in the most congested areas (Tuns et al., 2013);
- the prioritization of building consolidation, correlated with the buildings’ locations and their potential to block street segments and critical access routes in the event of their collapse;
- the re-evaluation of the number and locations of fire stations;
- the development of a system of emergency medical aid posts within the historic centre, taking into account both the area’s access problems and the fluctuating population of the area resulting from its entertainment role;
- reorganization of Colţea Hospital, including the expansion of its infrastructure (especially the surgical section, and the number of operating theatres). This hos-
pital should become the most important point of emergency intervention in the historic centre of Bucharest in the event of a strong earthquake.

6 Conclusions

This study demonstrates that GIS can be used effectively as an analytical and decision-making tool in planning for hazard mitigation. GIS, when properly employed, can provide information concerning emergency response accessibility in areas where physical structures are degraded and pose a higher risk of collapse. Such knowledge is critical in anticipating the impact of a disaster. Injury, loss of life, and damage to property can be minimized through more effective and rapid emergency response.

In Europe, Bucharest ranks second, after Istanbul, in its exposure and risk related to earthquakes. It is not enough to be familiar with the distribution of the high-seismic-risk buildings. Emergency intervention is also vital to minimize the consequences of such an event. In order to save lives, knowledge of accessibility levels and related rapid intervention potential is essential in the event of an earthquake. However, the current status and priorities of natural hazard and emergency response planning in the city of Bucharest (and at the national scale) are such that they are unlikely to mitigate the effects of a potential disaster to a sufficient extent. Across several measures – the training of specialists, public awareness and education, infrastructural improvements, and building improvements – current efforts are inadequate.

The passivity of urban decision makers in relation to the very large number of buildings in the highest risk class is perhaps the most surprising element here. These buildings are concentrated in the most populated and attractive areas of the city in terms of leisure and entertainment. Even if Bucharest’s inhabitants are partially aware of this risk, the vast majority of tourists are unlikely to realize what could happen should an earthquake occur.

The most recent major disaster event that took place in Bucharest – the fire in Club Colectiv on the night of 30 October 2015, which led to the deaths of 63 people and serious injury to around 150 – brought the major risk that an earthquake can pose to the attention of the local and national authorities. In response, a ban was imposed on all shops, restaurants, and clubs operating in buildings with high seismic risk, but there are not enough resources to refit the high-risk buildings that continue to be inhabited. This event reminded the population and the authorities that an earthquake event or disaster of similar scale will occur again at some point and that it is necessary to have a clearly defined policy that relies upon concrete measures to reduce the human and material losses.

Our study reveals both the importance of accessibility to buildings for emergency intervention and the shortcomings in the current provision of major emergency response services. Our methodology, using simple tools, offers analysts and decision makers a credible means of developing a proactive vision of and a management strategy for emergency response in congested historic areas. GIS is a commonly used tool for analyses of this type, and its results, since they can be expressed cartographically, can be more widely understood than is often the case when other statistical and computational techniques are employed.

Data availability. Lists of technically tested buildings in terms of seismic risk are freely available at http://amccrs.pmb.ro/docs/Lista_imobililor_expertizate.pdf (last access: 15 October 2017, Municipality of Bucharest, 2017).

Competing interests. The authors declare that they have no conflict of interest.

Author contributions. CM and II designed the study, GM, CM, and II established and set up the maps. II, CM, RJ, GM, and GP analysed and interpreted the results. II and CM wrote the paper with substantial input from all co-authors. RJ revised the English.

Acknowledgements. This work has been partially supported by the project UB 2008.
