Abstract. In this paper, typhoon simply means tropical cyclone. As risk is future probability of hazard events, when estimated future probability is the same as historical probability for a specific period, we can understand risk by learning from past events. Based on precipitation and wind data over the mainland of China during 1980–2014 and disaster and social data at the county level in Zhejiang Province from 2004 to 2012, a study on risk zoning of typhoon disasters (typhoon disasters in this paper refer to affected population or direct economic losses caused by typhoons in Zhejiang Province) is carried out. Firstly, characteristics of typhoon disasters and factors causing typhoon disasters are analyzed. Secondly, an intensity index of factors causing typhoon disasters and a population vulnerability index are developed. Thirdly, combining the two indexes, a comprehensive risk index for typhoon disasters is obtained and used to zone areas of risk. The above analyses show that southeastern Zhejiang is the area most affected by typhoon disasters. The annual probability of the occurrence of typhoon rainstorms >50 mm decreases from the southeast coast to inland areas, with a maximum in the boundary region between Fujian and Zhejiang, which has the highest risk of rainstorms. Southeastern Zhejiang and the boundary region between Zhejiang and Fujian provinces and the Hangzhou Bay area are most frequently affected by extreme typhoon winds and have the highest risk of wind damage. The population of southwestern Zhejiang is the most vulnerable to typhoons as a result of the relatively undeveloped economy, mountainous terrain and the high risk of geological disasters in this region. Vulnerability is lower in the cities due to better disaster prevention and reduction strategies and a more highly educated population. The southeast coastal areas face the highest risk of typhoon disasters, especially in the boundary region between Taizhou and Wenzhou cities. Although the inland mountainous areas are not directly affected by typhoons, they are in the medium-risk category for vulnerability.

1 Introduction

Typhoon, which means tropical cyclone in this paper, often causes some of the most serious natural disasters in China, with an average annual direct economic loss of about USD 9 billion. The arrival of a typhoon is often accompanied by heavy rain, high winds and storm surges, with the main impacts in southern coastal areas of China (Zhang et al., 2009). Zhejiang Province is seriously affected by typhoons – for example, in 2006, super-typhoon Sang Mei caused 153 deaths in Cangnan County in Wenzhou City, with CNY 11.25 billion of direct economic losses. Therefore it would be of practical significance to develop a system for the risk assessment of typhoon disasters in Zhejiang Province.

Major risk assessment models include the disaster risk index system of the United Nations Development Program (global scale, focusing on human vulnerability), the European multiple risk assessment (with emphasis on factors causing disasters and vulnerability) and the American Hazus-MH hurricane module and disaster risk management system. Vickery et al. (2009), Fang and Shi (2012), and Fang and Lin (2013) reviewed the factors causing typhoon disasters. Rain and wind are direct causes of typhoon disasters. Rain and wind are direct causes of typhoon disasters (Emanuel, 1988, 1992, 1995; Holland, 1997; Kunreuther and Roth, 1998); stronger typhoons produce heavier rain and stronger winds, resulting in a greater number of casualties.
and higher economic losses. Many of the studies on the factors causing typhoon disasters used a grade index and the probability of occurrence (H. Y. Chen et al., 2011; Su et al., 2008; Ding and Shi, 2002; Chen, 2007). Recently, some studies built quantitative assessments in some provinces and carried out preliminary studies on pre-evaluating typhoon disasters (Huang and Wang, 2015; Yin and Li, 2017).

In terms of vulnerability, Pielke and Landsea (1998) and Pielke et al. (2008) combined the characteristics of typhoons and socioeconomic factors, suggesting that both the vulnerability of the population and economic factors were important in estimating disaster losses. The vulnerability of a population is a preexisting condition that influences its ability to face typhoon disasters. Among the most widely used indexes is the Social Vulnerability Index (SoVI) (Cutter et al., 2003; W. F. Chen et al., 2011). Other researches have focused on the vulnerability of buildings, obtaining a fragility curve by combining historical loss with the characteristics of buildings and typhoons (Hendrick and Friedman, 1966; Howard et al., 1972; Friedman, 1984; Kafali and Jain, 2009; Pita et al., 2014). Studies in China have assessed vulnerabilities to typhoon disasters (Yin et al., 2010; Niu et al., 2011). Evaluation indexes for the assessment of disaster losses were established based on the number of deaths, direct economic losses, the area of crops affected and the number of collapsed houses. These indexes were used to construct different disaster assessment models (Liang and Fan, 1999; Lei et al., 2009; Wang et al., 2010). Xu et al. (2015) comprehensively assessed the impact of typhoons across China using the geographical information system. The future direction of tropical cyclone risk management is quantitative risk models (Chen et al., 2017).

Previous studies have concentrated on semiquantitative large-scale research, with less emphasis on quantitative research at the county level based on large numbers of accurate data. In addition, the studies have paid more attention to disaster losses. Few studies have focused on a comprehensive risk assessment of typhoon disasters coupled with factors causing typhoon disasters and population vulnerability. In this study, Zhejiang Province, which is frequently affected by the strongest landfall typhoons (Ren et al., 2008) and experiences most serious typhoon disasters (Liu and Gu, 2002) on the mainland of China, is selected as the study area. This paper does not consider the impact of storm surges. The factors causing typhoon disasters are represented by typhoon rain and typhoon wind. Section 2 introduces the data and methods used in this study. Section 3 provides analyses on typhoon disaster losses and factors causing typhoons. Section 4 presents risk assessment and regionalization of typhoon disasters. Summary and discussions are given in the final section.

2 Data and methods

This study is carried out in Zhejiang Province (Fig. 1) including 11 cities along the Yangtze River Delta. Zhejiang Province borders the eastern part of the East China Sea, is adjacent to Fujian Province, and is one of the most economically powerful provinces in China.

2.1 Data

2.1.1 Typhoon, precipitation and wind data

The typhoon data used in this study are the best-track tropical cyclone datasets from the Shanghai Typhoon Institute for the time period 1960–2014 (Eunjeong and Ying, 2009; Li and Hong, 2015). Daily precipitation data for 2479 stations and daily wind data for 2419 stations during the time period 1960–2014 over the mainland of China are obtained from the National Meteorological Information Center. The maximum wind speed is given as the maximum 10 min mean. In this paper, two time periods of precipitation and wind data are used.

Because of limited access to county-level typhoon disaster data, we have only obtained data from 2004 to 2012. So when calculating intensity index of factors causing typhoon disasters, the time period of typhoon precipitation and typhoon wind is the same as for the typhoon disasters and is 2004–2012.

For risk analyses of typhoon precipitation and typhoon wind (please see details in Sect. 3.1 and 3.2), estimated future probability is the same as historical probability, and we then select the period of 1980–2014. As Lu et al. (2016) mentioned, considering the homogeneity of wind data, we use the period of 1980–2014 for wind analysis. To ensure the consistency between wind and precipitation data, 1980–2014 is selected as the period. In addition, the objective synoptic analysis technique (OSAT) is needed to identify typhoon wind and precipitation from a wider range than just Zhejiang Province (please see details in Sect. 2.2.1); thus 2419 stations of precipitation data and 2479 stations of wind data over mainland China are used, 71 stations of which correspond to counties in Zhejiang Province.

2.1.2 Disaster and social data

Disaster data for each typhoon that affected Zhejiang Province from 2004 to 2012 are obtained from the National Climate Center and the number of records for each county is shown in Fig. 2. Of the 11 cities in Zhejiang Province, Wenzhou and Taizhou record the most typhoon disasters, with the maximum being 17 at Wenzhou. Fewer typhoon disasters are recorded in the central and western regions of Zhejiang Province, particularly in Changshan and Quzhou, which may be because the strength of typhoons weakened after landfall. The population data in 2010 are obtained from the sixth national population census (Population Census Office of the
2.2 Methods

2.2.1 Objective synoptic analysis technique

The widely used the OSAT proposed by Ren et al. (2001, 2007) and Ren and Wu (2011) is used to identify precipitation due to typhoons in this study. The OSAT is a numerical technique to separate tropical-cyclone-induced precipitation from adjacent precipitation areas. Based on structural analysis of precipitation fields, it can be divided into different rain belts. Then, according to the distances between a typhoon center and these rain belts and the typhoon center and each station, typhoon precipitation is distinguished. Lu et al. (2016) improved the OSAT and applied it to identify typhoon winds. With the application of the OSAT method, daily precipitation and wind data over the mainland of China from 1980 to 2014 are used for identifying typhoon precipitation and wind data.

2.2.2 Canonical correlation analysis (CCA)

We use the canonical correlation analysis method (CCA) to determine the relationship among the affected population, the rate of economic damage, and typhoon precipitation and winds. In statistics, CCA is a way of inferring information from cross-covariance matrices. If we have two vectors $X = (X_1, \ldots, X_n)$ and $Y = (Y_1, \ldots, Y_m)$ of random variables, and there are correlations among the variables, then CCA can find linear combinations of $X_j$ and $Y_j$, which have a maximum correlation with each other (Hardoon et al., 2014). The method was first introduced by Hotelling in 1936 (Hotelling, 1936). The main point of CCA is to separate linear combinations of new variables from the two sets of variables. In this

Figure 1. Maps of Zhejiang Province, China, showing location and major cities.

Figure 2. Number of records of typhoon disasters in Zhejiang Province from 2004 to 2012.
2.2.3 Data standardization

We adopt two methods: Z-score standardization and min–max standardization. The Z-score standardized method is based on the mean and standard deviation of the raw data, which is the precondition for the CCA method. The min–max standardization is a linear transformation of the original data so that the original value maps the interval [0, 1]. Z-score standardization is used for calculating the intensity index of factors causing typhoon disasters. Both typhoon precipitation and typhoon maximum wind speed are standardized by this method. When calculating the comprehensive typhoon disaster risk index ($R$), we use min–max standardization to standardize the intensity index of the factors causing typhoon disasters ($I$) and the population vulnerability index (SoVI).

2.2.4 Vulnerability assessment (SoVI, PCA)

County-level socioeconomic and demographic data are used to construct an index of social vulnerability to environment.
tal hazards named the SoVI. Principal component analysis (PCA) is the primary statistical technique for constructing the SoVI. The PCA method captures multidimensionality by transforming the raw dataset to a new set of independent variables. Then a few components can represent the dimensional data, and underlying factors can be identified easily. These new factors are placed in an additive model to compute a summary score – SoVI (Cutter et al., 2003). Based on various SoVIs derived for disaster social vulnerability in America, Chen et al. (2014) collects 29 variables as proxies to build a set of vulnerability indexes for the social and economic environment in China. We then use these vulnerability indexes to calculate the population vulnerability index for Zhejiang Province.

3 Typhoon disaster losses and factors

Based on the distribution of typhoon disaster losses in Zhejiang Province from 2004 to 2012 (Fig. 3), the affected areas are mainly located in the southeast corner of the province. The centers with the largest affected population (Fig. 3a), the largest area of affected crops (Fig. 3c) and the highest direct economic losses (Fig. 3d) are in Wenzhou and Taizhou cities, although the losses in Ningbo City are also relatively high. Cangnan in Wenzhou City is the most severely affected, with the highest cumulative death toll (Fig. 3b). According to the statistical yearbooks of each city in Zhejiang Province, Jiaxing, Shaoxing, Hangzhou in the northeast, and Wenzhou, Jinhua and Taizhou in the southwest are the regions with the largest agricultural planting area, with more agricultural population in the southwest. Only parts of the plain area were affected by serious agricultural disasters in the northeast. The agricultural disaster areas in the southwest are wider (Fig. 3c). According to the main indicators of Zhejiang’s national economy (total GDP and per capita GDP), central cities such as Hangzhou in the northeast had the most developed economy, and the urban economies of

Wenzhou and Taizhou in the southwest were also relatively good. However, the economic losses in southwestern Zhejiang are severe, much higher than in the northeastern cities (Fig. 3d). The losses in the affected counties are associated with the frequency and intensity of typhoons. We therefore analyze the risk of typhoon precipitation and winds in every county in Zhejiang Province to provide a reference dataset for the factors causing typhoon disasters.

3.1 Probability of typhoon rainstorms

The main hazard of typhoon precipitation is concentrated precipitation, so the average duration (days) of typhoon precipitation at each station in Zhejiang Province is counted from 1980 to 2014 (Fig. 4). The duration of typhoon rainfall is less in inland areas, especially in Quzhou City. Persis-
tent precipitation is concentrated in Wenzhou, Taizhou and Ningbo cities, where there may have been a higher risk of typhoon disasters. Typhoon rainstorm in this study means daily typhoon precipitation over 50 mm, and typhoon torrential rainstorm means daily typhoon precipitation over 100 mm. The probability is the annual possibility of the occurrence of typhoon rainstorms. The probability denominator is the total number of years, and the numerator is the annual frequency of typhoon precipitation. If a station experiences typhoon precipitation in 1 year, the numerator increases by 1. Based on the probability of typhoon rainstorms occurring in each county in Zhejiang Province (Fig. 5), we found that the annual probability of the occurrence of typhoon rainstorms is highest over the southeast coast of Zhejiang Province from 1980 to 2014, especially in Taizhou City, where the annual probability is 83%. The annual probability of typhoon rainstorms with precipitation >100 mm is lower, but the distribution of probability is consistent with the rainstorms with lower precipitation. The probability of typhoon torrential rainstorms decreases rapidly in the western and central regions of Zhejiang Province, although the range increases. There are three centers of high probability: Taizhou, Wenzhou and Ningbo cities.

3.2 Probability of typhoon winds

The average duration (days) of typhoon winds (over grade 6) is calculated in Zhejiang Province (Fig. 6). The duration of typhoon winds is relatively short in the central and western regions and the typhoon winds are concentrated in the coastal areas of Wenzhou, Taizhou and Ningbo cities. The longest duration of typhoon winds occurs over the offshore islands.

The main hazard from typhoon winds is manifested in the destructive force of strong winds. Therefore, we calculate the probability of annual occurrence of typhoon winds at or above grades 6 and 12 at each station from 1980 to 2014 (Fig. 7). Typhoon winds at or above grade 6 mainly occur along the coastal areas, with a rare occurrence in the mountainous areas. Meanwhile, the probability of typhoon winds at or above grade 8 is generally 0.5–0.9 along the coast and below 0.25 in the inland mountainous areas. Typhoon winds at or above grade 10 or 12 are much less likely and are only seen around the coastal areas and islands, with a rapidly decreasing probability from the coastal areas to the inland mountainous areas. The areas with a high probability of typhoon winds are consistent with those with a high probability of typhoon rain, i.e., Wenzhou, Taizhou and Ningbo cities. The probability of typhoon extreme winds is much higher in coastal areas than inland.
4 Risk assessment and regionalization of typhoon disasters

4.1 Intensity index of factors causing typhoon disasters

The main factors causing typhoon disasters, which are considered in this study, are rainstorms and winds. The level and intensity of a single factor cannot fully represent and describe the impact. It is necessary to determine their influence through typical correlation analysis, and then typhoon wind and rain effect are superimposed by the weight coefficients. Therefore, we establish a comprehensive intensity index that includes typhoon precipitation and winds. Taking the county as a unit, we select all the typhoons that affected the population of Zhejiang Province from 2004 to 2012. The total precipitation and daily maximum wind speed during typhoons measured in each county are used to describe the factors causing typhoon disasters. The total sample size is 322. Using CCA, we determine the impact of typhoon precipitation and winds on the population. We then perform CCA for all the typhoons that caused direct economic losses in Zhejiang Province from 2004 to 2012, and the total sample size is 404 (Table 1). The effect of typhoon precipitation on both the population and direct economic losses is always greater than that of typhoon winds. By averaging typical coefficients for both precipitation and wind, weight coefficients of 0.85 and 0.65 are obtained within the intensity index for precipitation and winds, respectively.

Based on the weight coefficients in Table 1, an intensity index of factors causing typhoon disasters is established:

\[ I = Ax + By, \]

where \( I \) is the intensity index of factors causing typhoon disasters, \( X \) is the standard typhoon precipitation and \( Y \) is the maximum wind speed of the typhoon. \( A \) and \( B \) are the weight coefficients for typhoon precipitation and typhoon winds, respectively. Using Eq. (1), we average the intensity indexes of typhoons at each station (Fig. 8). Based on the distribution of these average intensity indexes, three high-value centers, namely Wenzhou, Taizhou and Ningbo cities are identified, which is consistent with the results of H. Y. Chen et al. (2011).

4.2 Population vulnerability index

Natural disasters are social constructions and the basic causes of losses are the attributes of human beings and their social system (Jiang, 2014). The index system of W. F. Chen et al. (2011) is used to evaluate the vulnerability of Zhejiang Province. Based on the extracted population information, 29 variables are identified that may affect vulnerability (Table 2).

After PCA of the 29 variables, seven components with an eigenvalue >1 are extracted. Based on the variable meanings in each component, these seven components are named in Table 3. The first component, which reflects the income of the population and the employment situation, contributes 30.1 % of the total variance. This component is positive because the more property there is in an area, the higher the vulnerability to damage. The second component, which reflects education level of the population, occupies 15.6 % of the total variance. This component is negative because if education level is higher, then the population’s awareness of disaster prevention and reduction is greater and their vulnerability is lower. The third component, which reflects the number of dilapidated houses, takes up 8.7 % of the total variance. This component plays a positive part in vulnerability. The fourth component, which reflects the illiteracy and the number of young people, is positive and represents 8.4 % of the total variance. The fifth component, which reflects the household size and the percentage of women, explains 7.7 % of the total variance and is positive. The sixth component, which reflects the number of ethnic minorities, contributes 6.1 % of the total variance and is positive. The seventh component, which represents 5.3 % of the total variance, reflects the unemployment rate and the housing area and is positive.

The total variance explained by these seven components is up to 81.9 %, which can be used to represent the population vulnerability of Zhejiang Province. The distributions of the first (positive) component and the second (negative) component are shown in Fig. 9. Areas with a low employment rate have high vulnerability, but the vulnerability is low in urban areas with higher levels of education. The seven components thus represent the real vulnerability of the population in Zhejiang Province to the effect of typhoons. The population vulnerability index in Zhejiang Province (SoVI) is calculated as

Figure 10. Distribution of population vulnerability index of counties.

SoVI = component 1 − component 2 + component 3 + component 4 + component 5 + component 6 + component 7.

By calculating the vulnerability indexes of each county, the distribution of population vulnerability in Zhejiang Province is obtained (Fig. 10). The areas with high vulnerabilities are mountainous regions where the economy is relatively undeveloped, whereas the vulnerability is low in cities, such as Hangzhou and Huzhou cities, where there is a greater awareness of disaster prevention and reduction and houses are of high quality.

4.3 Comprehensive typhoon disaster risk index and zoning

The typhoon disaster risk assessment system is mainly composed of the factors causing disasters, the population vulnerability and the environment. In this paper, comprehensive typhoon disaster risk index is obtained by combining the factors causing typhoon disasters and vulnerability, without taking the sensitivity of the environment into account. After standardizing the intensity index of factors causing typhoon disasters and the population vulnerability index, the comprehensive typhoon disaster risk index ($R$) is obtained as follows:

$$R = \text{intensity index of factors causing typhoon disasters} \times \text{vulnerability index (SoVI)}.$$  

Based on the comprehensive risk index, five risk grades for typhoon disasters are defined (Table 4), and risk zoning of typhoon disasters in Zhejiang Province has been carried out as shown in Fig. 11. The classification of typhoon disaster risk index is based on the natural breaks method provided by ArcGIS.

Figure 11 shows that the index presents a good reflection of the distribution of typhoon disasters in Zhejiang Province (Fig. 3), especially in the southeastern coastal areas. The southeastern coastal areas face the highest risk, especially in the boundary regions between Zhejiang and Fujian provinces, and Taizhou and Wenzhou cities. Overall, the risk of typhoon disasters decreases from the coast to inland areas. Cities are at medium to low risk as a result of their developed economy, high-quality houses and better-educated population. The inland mountainous areas have a high vulnerability. Although they are not directly affected by typhoons, they are still in the middle risk areas as a result of their poorly developed economy.

5 Discussion and conclusions

1. An intensity index of factors causing typhoon disasters is developed, with the highest values in Wenzhou, Taizhou and Ningbo cities. A comparison between the distributions of the intensity index and actual typhoon disasters in Zhejiang Province from 2004 to 2012 shows that the index is a good reflection of the possibility of typhoon disasters.

2. Seven components are extracted after PCA of 29 variables affecting vulnerability. These seven factors represent 81.9% of the total variance and are a good reflection of the index of population vulnerability in Zhejiang Province. Southwestern Zhejiang is the most vulnerable as it has a relatively undeveloped economy, more mountainous areas and a higher risk of geological disasters. Vulnerabilities are lower in cities as a result of
better disaster prevention and reduction measures and a better-educated population.

3. The comprehensive typhoon disaster risk index is obtained by combining the factors causing typhoon disasters and population vulnerability. Based on the comprehensive risk index, risk zoning of typhoon disasters in Zhejiang Province is achieved. The southeastern coastal areas are at high risk, especially the boundary regions between Zhejiang and Fujian provinces and Taizhou and Wenzhou cities. The risk of typhoon disasters decreases quickly from coastal areas to inland regions. Cities are at medium to low risk because of their developed economy, high-quality houses and better-educated population.

4. Although some interesting results have been obtained in this study, there are still some problems that require further study. As a result of the limited data on typhoon disasters, it is currently impossible to give a long time trend for high-resolution typhoon disaster analysis. It is also unclear whether this methodology can be applied to other regions. This paper mainly considers the effects of typhoon rain and typhoon wind, without considering the impact of storm surge. This is the limitation of the study, and we will explore the role of storm surges in future work.

Data availability. The typhoon data used in this study are the best-track tropical cyclone datasets from Shanghai Typhoon Institute, which can be obtained from http://hcd ata.typhoon.org.cn/zhjsjj_zlhq. html (last access: November 2018). Daily precipitation data and daily wind data during the time period 1960–2014 over the mainland of China are obtained from the National Meteorological Information Center. Due to the data privacy policy of research institutions, these data are not publicly available. Disaster data for each typhoon that affected Zhejiang Province from 2004 to 2012 are obtained from the National Climate Center; because of the data privacy policy of research institutions, these data are also not public. The population data in 2010 are obtained from the sixth national population census, which can be obtained from http://www.stats.gov.cn/tjjsj/pcsj/rkpc/brp/indexch.htm (last access: November 2018). The 2010 statistical yearbooks of each city in Zhejiang Province are from http://tjj.zj.gov.cn/col/col1525563/indexch.htm (last access: November 2018), which are published by the cities’ statistical bureaus.

Author contributions. All co-authors took part in the research. While FR mainly conceived the idea, YL mainly developed the study methods and performed the calculations. YL prepared the paper with contributions from all the co-authors.

Competing interests. The authors declare that they have no conflict of interest.
